Abstract

In this study, the effect of cold temperature on the physical activity profiles of professional soccer players in official match-play was investigated. Computerised motion-analysis was used to analyse performance in 9 players (4 defenders and 5 midfielders) in four temperature ranges: $\leq 5^{\circ}\text{C}$ (29 matches), $6\text{--}10^{\circ}\text{C}$ (62 matches), $11\text{--}20^{\circ}\text{C}$ (48 matches) and $\geq 21^{\circ}\text{C}$ (27 matches). Performance was analysed per minute for total distance covered and distance run in three categories: $0.0\text{--}14.3\text{ km/h}$ (walking/low/moderate); $14.4\text{--}19.7\text{ km/h}$ (running); $\geq 19.8\text{ km/h}$ (high-intensity). Results showed that while total distance run per minute was unaffected in colder conditions, midfielders ran significantly shorter distances in warmer temperatures: $\geq 21^{\circ}\text{C} = 118.7 \pm 6.9\text{m}$ versus $\leq 5^{\circ}\text{C} = 124.2 \pm 7.1\text{m}$, $p < 0.01$; $6\text{--}10^{\circ}\text{C} = 123.6 \pm 6.8\text{m}$, $p < 0.01$; and, $11\text{--}20^{\circ}\text{C} = 123.4 \pm 5.4$, $p < 0.05$). The total distance covered at three intensities and across halves was unaffected by temperature. Similarly, high-intensity efforts across match halves and in the first and final 5-minute periods in each half of normal time were unaffected by temperature. In contrast, high-intensity efforts in midfielders across 15-minute intervals were affected by temperature with greater distances covered per minute in the 30–45 minute period in matches played in temperatures $\leq 5^{\circ}\text{C}$ versus the corresponding period in those played in temperatures $\geq 21^{\circ}\text{C}$ ($9.1 \pm 3.8\text{m}$ versus $6.2 \pm 3.0\text{m}$, $p < 0.05$). The present findings generally suggest that physical performance in professional soccer does not decrease in cold temperatures.

Key words: performance, temperature, motion analysis, football

Introduction

Soccer training and competition are often performed by players in unfavourable environments. Indeed, there are three major environmental conditions that raise concerns in relation to soccer performance: high altitude, heat and humidity, and cold [4]. For example, altitude negatively impacts physical performance by impairing aerobic power and delaying recovery of high-energy phosphates between high-intensity "interval" type efforts [14]. Two recent studies [11,13] have also attempted to address the issue of high ambient temperatures on physiological responses and physical activity profiles in soccer competition. A pronounced reduction in high-intensity running was observed toward the end of a friendly game (-54% in the final compared to the first 15-minute period) played by professional Spanish soccer players in a hot environment ($\sim 31^{\circ}\text{C}$) [11]. Second-half high-intensity running performance in Turkish semi-professional players was also shown to be substantially affected in two games played in temperatures $>30^{\circ}\text{C}$ (mean decrease of 19%) [13]. Thermal stress and dehydration were factors linked to the drop in performance. However, these studies examined the effects of temperature on performance in one or two matches. The inherent variability in running performance in match-play means that research requires larger sample sizes in order to detect real systematic changes in characteristics of performance [6].

The issue of training and playing soccer in cold conditions has not been studied in a satisfactory manner [4]. A decrease in muscle temperature can affect the ability to produce dynamic explosive contractions [12] inducing significant decreases in sprinting ability [10]. Explanations for impaired muscle performance in the cold include a decreased mechanical efficiency of muscles and vasoconstriction leading to a reduced oxygen delivery [12]. Yet, it is unknown to what extent cold will influence physical activity patterns in intermittent endurance type sports such as soccer. In light of this, information on the impact of playing soccer in cold temperatures on key aspects of performance such as the total distance run and that covered in high-intensity running and on work-rate across different match periods could be useful to inform subsequent preparation strategies. Consequently, the aim of this study in French professional soccer players was to investigate the effect of cold temperatures on physical activity profiles during official competition.

Material and methods

Participants and match sample

Physical performance in official competition was analysed for players from a professional soccer team that competed in the French Ligue 1 (top-flight division). While this study meets the ethical standards of the International Journal of Sports Medicine [7], these data arose as a condition of employment in which player performance was routinely measured over the course of the competitive season [15]. Therefore, usual appropriate ethics committee clearance was not required. Nevertheless, to ensure team and player confidentiality, all performance data were anonymised before analysis.

Altogether, performance in 80 French League 1 games over four seasons (2007/2008: $N=16$, 2008/2009: $N=26$, 2009/2010: $N=26$, 2010/2011: $N=12$) was analysed. The sample included 50 home and 30 away matches in which players completed the entire match and played in their customary role. A total of 4 defenders and 5 midfield players were included for analysis leading to 173 and 166 instances of match performance respectively. Forward players were not included due to insufficient numbers of games completed in different temperatures.

Data collection procedures and measures of competitive performance

Measures of ambient temperature within a 1-hour period prior to kick-off in French Ligue 1 games are systematically taken by match-day officials belonging to the French Professional Football League [8]. The present measures were subsequently obtained from the League. The following temperature classification was employed: $\leq 5^{\circ}\text{C}$ = very cold, $6\text{--}10^{\circ}\text{C}$ = cold, $11\text{--}20^{\circ}\text{C}$ = moderate and $\geq 21^{\circ}\text{C}$ = warm. In defenders and midfielders respectively, 28 and 29 instances of performance were collected at temperatures $\leq 5^{\circ}\text{C}$, 70 and 62 instances at $6\text{--}10^{\circ}\text{C}$, 49 and 48 instances at $11\text{--}20^{\circ}\text{C}$ and 26 and 27 instances at $\geq 21^{\circ}\text{C}$.

A semi-automatic computerised player tracking system (AMISCO Pro®, Sport-Universal Process, Nice, France) was used to analyse physical activity profiles in official match-play. This multiple-camera system passively tracks the movements of every player using a sampling rate of 10.0 Hz over the entire course of matches. The workings, accuracy and reliability of this system in measuring player movements in elite soccer competition have been described in detail elsewhere [2].

The measures of physical performance selected for the analyses included the total distance covered and the distance covered in three categories of movement intensity: $0.0\text{--}14.3\text{ km/h}$ (low/moderate); $14.4\text{--}19.7\text{ km/h}$ (running); $\geq 19.8\text{ km/h}$ (high-intensity) [3]. The overall duration of matches and halves frequently varied. Therefore, all distances covered are presented as the distance covered per minute (distance divided by duration of entire match or individual match period). A drop in high-intensity running performance is frequently observed at the end compared to the beginning of match halves (2). Therefore, distances covered at high-intensities were compared across selected intervals in normal match time: 0-5mins, 40-45mins, 45-50mins and 85-90mins, and; 0-15mins, 15-30mins, 30-45mins, 45-60mins, 60-75mins and 75-90mins.

Statistical Analyses

All statistical analyses were conducted using SPSS for Windows Version 14.0 (SPSS Inc., Chicago, IL, USA). Results are reported as means and standard deviations (mean $\pm$ SD). Two-way ANOVAs were used separately for each playing position to compare overall performance across temperatures ranges and to identify the interactions between temperature and distance covered at various running intensities and across selected match periods. Follow-up univariate analyses using Bonferroni-corrected pair wise comparisons were used where appropriate. Statistical significance was set at $p < 0.05$.

Results

In defenders, the total distance run was similar across all four temperature ranges ($p = 0.135$) whereas a difference in performance was observed in midfielders ($p = 0.002$). A longer overall distance was covered by the latter in games played in all temperatures compared to those in temperatures $\geq 21^{\circ}\text{C}$ (see Table 1). Temperature did not influence the distances covered at three individual running intensities in defenders ($p = 0.943$) or midfielders ($p = 0.271$).

The comparison of match halves (Table 1) showed that the total distance run varied across halves in defenders and midfielders (both $p < 0.001$) as significantly more distance was run in the first- versus the second-half in all temperatures ranges (statistical differences ranged from $p < 0.05$ to $p < 0.001$). However, performance in each respective half was not influenced by temperature in either defenders ($p = 0.439$) or midfielders ($p = 0.685$). In all temperatures, the distance run at high-intensities did not change between halves in either defenders ($p = 0.269$) or midfielders ($p = 0.625$) and performance in each respective half was not affected by temperature (defenders: $p = 0.847$; midfielders: $p = 0.994$).

Insert Table 1 about here.

The total distance covered varied across 15-minute game intervals for matches played in all four temperature ranges in defenders and midfielders (both $p < 0.001$). However, no interaction was observed between temperature and performance across individual match intervals (defenders: $p = 0.446$, midfielders: $p = 0.125$) (Table 2). While the distance covered by defenders in high-intensity running across 15-minute intervals varied for all four temperature ranges ($p < 0.001$) this was not influenced by temperature ($p = 0.854$). In midfielders, the distance covered in high-intensity running across 15-minute intervals did not vary ($p = 0.413$) but was dependent upon temperature ($p = 0.009$) as more distance was covered in the 30-45 minute period in matches played at temperatures $\leq 5^{\circ}\text{C}$ compared to the corresponding period in matches played at temperatures $\geq 21^{\circ}\text{C}$ ($p < 0.05$). In addition, more distance was covered at high-intensities in the 75-90 minute period in matches played at temperatures from $11\text{--}20^{\circ}\text{C}$ compared to the corresponding period in matches played at $6\text{--}10^{\circ}\text{C}$ ($p < 0.05$).

Insert Table 2 about here.

In both defenders ($p = 0.038$) and midfielders ($p = 0.016$), the total distance covered in high-intensity running varied across selected 5-minute game intervals in normal time for matches played in different temperatures. In midfielders, a greater distance ($p < 0.05$) was covered in games played at $11\text{--}20^{\circ}\text{C}$ for the first 5-minutes of play compared to the final 5-minutes of play in normal time of the first half (40-45mins) (Table 2). No significant post hoc differences were obtained in defenders. No interaction was observed between performance and temperature for any of the 5-minute intervals in either defenders ($p = 0.604$) or midfielders ($p = 0.546$).

Discussion

In this study, an investigation into the effects on physical activity profiles of playing professional soccer in a cold environment was conducted. The main finding is that cold weather was not detrimental to overall physical performance (total distance and distances covered at three running intensities) in defenders and midfielders and that first and second-half running performance was unaffected in cold conditions. While the total distance covered across 15-minute match intervals was unaffected in colder temperatures, a significant difference in performance in high-intensity running across intervals was observed in midfielders. In contrast, high-intensity running performance in the first and final 5-minute periods in each half of normal time was unchanged in cold temperatures.

In many European countries, soccer is often played in near freezing conditions which are frequently associated with a reduction in core and muscle temperature in participants [14]. Subsequently, characteristics specific to soccer performance such as muscular strength and power output may be affected. Similarly, prolonged exercise in very cold conditions ($< 5^{\circ}\text{C}$) may also lead to dehydration and reduced high-intensity endurance performance [1]. In this study, endurance performance characterised by the total distance run was significantly related to ambient temperature. However, performance was impaired in hot but not in cold conditions. In addition, the total distance covered at three different speed intensities was unaffected by temperature. These results suggest that overall work-rate activity profiles and the capacity to perform intermittent exercise in these elite players were not adversely affected in cold conditions. The average exercise intensity during soccer match-play is estimated to be $75\% \text{VO}_{2\text{ max}}$ [14]. This intensity may be sufficient to offset the deleterious effects of a cold environment on body temperature as related research showed that performance in endurance

exercise at an intensity of 70% $\text{VO}_{2\text{ max}}$ in a cold environment (4°C) was similar to that performed in moderate temperatures (11°C) [5]. Nevertheless, the total distance covered by midfield players was significantly lower in warmer temperatures ($\geq 21^{\circ}\text{C}$) partly confirming previous findings [11,13] that warmer environments can have a detrimental impact on work-rate performance in competitive soccer.

Research in elite soccer generally shows that players cover lower total distances in the second-half of competition and that physical performance can vary substantially across different periods of the game [2]. In the present players, a reduction in the total distance covered in the second compared to the first half and a significant variation in the total distance covered across 15-minute intervals were common to matches played in all temperatures. However, the differences in total distance run in the second-half and that across 15-minute intervals was not related to temperature suggesting that overall running performance in the second-half and in different periods of the game is unimpaired when performing in cold (and warm) temperatures. This result may be linked to nutritional and/or pacing strategies which enabled the present players to adequately respond to match-play demands throughout [3]. It may also be linked to the physical demands imposed by opponents who also adjusted their physical efforts according to the environmental conditions.

The analysis of high-intensity efforts showed that performance across halves and in the 5-minute period at the start and end of normal time in each half was unaffected by temperature. In contrast, high-intensity performance across 15-minute intervals in midfielders was dependent upon temperature. Players covered a significantly greater distance in the 30-45 minute period in matches played at $\leq 5^{\circ}\text{C}$ compared to the corresponding period in those played at $\geq 21^{\circ}\text{C}$. In addition, in games played at lower temperatures ($\leq 5^{\circ}\text{C}$ and $6-10^{\circ}\text{C}$), the distance covered by midfield players in high-intensity running progressively increased for each 15-minute period reaching its maximum just before half-time (30-45mins) whereas in moderate ($11-20^{\circ}\text{C}$) and warm ($\geq 21^{\circ}\text{C}$) temperatures, performance was at its maximum at the beginning of games (0-15mins) and then progressively decreased until half-time. This result suggests that in cold temperatures, high-intensity running performance in midfielders is to some extent affected at the beginning of games and may only reach its optimum towards the end of the first-half. An investigation into the effectiveness of pre-match warm-up regimens in a range of temperatures is therefore merited as is a study examining the effects of duration and intensity of cold exposure prior to and during exercise as these can impact subsequent physical performance [9].

Limitations of this study included the lack of information on additional environmental factors such as relative humidity and wind-chill and changes in climatic conditions over the course of games. In addition, planning for performance in the cold requires an understanding of the mechanisms underpinning the physiological response [12]. Measures of dehydration, heart rate and thermal responses and the relationship between match activity and fitness test profiles are warranted to provide additional information on the physiological strain specific to competitive play in cold environments. Finally, controlled laboratory simulations of soccer match-play could be conducted in an attempt to determine the effects of individual anthropometric characteristics (e.g., body fat percentage and body surface area) and clothing status (thermal protective garments) when performing in a cold environment.
